Abstract

This paper analyses the effects of sterilised, intraday foreign exchange market operations (non-discretionary and discretionary) on foreign exchange returns and volatility in four inflation targeting economies in Latin America. The distribution of exchange rates during intervention and non-intervention days are first compared, and then event study regressions are used to estimate the impact of intervention (and macro surprises) on exchange rate returns and exchange rate volatility as well as on foreign exchange market turnover (in Colombia). In general, the results suggest that the impact of both non-discretionary and discretionary operations is at times significant but transitory. However, an analysis of Chile’s experience suggests that the announcement effects of even non-discretionary programmes may be significant and persistent.

Introduction

An ongoing issue in Latin America and other emerging market economies (EMEs) is how to cope with cycles in capital inflows and outflows and the resulting pressures on the exchange rate. Extended periods of capital inflows are associated with currency appreciation pressures, which raise well known concerns including the risk of adverse effects on the tradable goods sector, deterioration of current account balances, the formation of asset price bubbles, excessive foreign indebtedness and increasing financial fragility. Episodes in which capital inflows reverse also raise concerns.

In this setting, Latin American authorities have had to choose between the possible costs of allowing the exchange rate to fluctuate freely, or trying to dampen exchange rate volatility or mitigate its effects through operations – or intervention – in the foreign exchange market. Latin American central banks have chosen to intervene in foreign exchange market operations for extended periods.

One motive is to accumulate foreign reserves for precautionary reasons during periods of foreign currency inflows or exchange rate appreciation, in order to then deploy these reserves during episodes of financial stress when the supply of foreign currency suddenly declines. Episodes of stress may be associated with “sudden stops” in cross-border financing, and sharp depreciation pressures, which can damage the financial and the real sectors, particularly in the presence of currency mismatches in which foreign currency liabilities are not hedged. Even in less extreme situations, the availability of foreign currency liquidity may be lower and related costs of foreign currency financing may be higher during periods of depreciation pressures.

Another motive is to influence the exchange rate, specifically to dampen exchange rate volatility or to reduce deviations from some perceived or estimated equilibrium exchange rate. Policymakers in the region who have adopted inflation targeting regimes stress that they do not seek to target the exchange rate level.

Foreign exchange market intervention raises important issues. These include possible incompatibility with the monetary framework (eg the exchange rate could compete with the inflation rate as a primary target), significant quasi-fiscal costs, and effectiveness in achieving its goals (eg financial stability or reduced exchange rate volatility).

The present paper focuses largely on the issue of effectiveness. It addresses the following questions: (i) What are the effects of intervention on the exchange rate? (ii) Are the effects persistent or transitory? (iii) Are any effects more apparent on the foreign exchange returns or their volatility? (iv) Do the effects of intervention differ when goals (to buy or sell fixed amounts of foreign currency or to influence the exchange rate) or intervention approaches (eg discretionary vs non-discretionary)

7 In this paper, we will use the terms “foreign exchange market intervention” and “operations” interchangeably. Some use the term “intervention” to apply only to those foreign exchange market operations whose objective is explicitly to influence the exchange rate. However, not all of the goals of foreign exchange operations are always made public, and even operations that are not intended to influence the exchange rate may do so. As a result, it is not always obvious where to draw the line. For a discussion of these terms and issues, see Moreno (2005).
are not the same? (v) What are the implications of intervention for market turnover? (vi) Do announcements of foreign exchange operations matter?

In order to shed light on these questions, this paper uses intraday data on exchange rate returns or turnover in foreign exchange markets, macroeconomic announcements and foreign exchange operations by central banks in four Latin American countries: Chile, Colombia, Mexico and Peru. As some of the data are confidential, the results are estimated for each foreign exchange market by central bank authors using a common methodology based on the work of Kathryn Dominguez (1999, 2003, 2006). As for the announcements, we present some data from Chile that suggest a significant market response.

The analysis involves the following elements:

- We describe the distributional properties of the intraday exchange rate data, and compare the first four moments of the distribution of exchange rates during intervention and non-intervention days.
- We run event study regressions to estimate the impact of intervention (and macro surprises) on exchange rate returns and exchange rate volatility.
- We use the event study regressions to estimate the impact of intervention (and macro surprises) on foreign exchange market turnover. (Results are available only for Colombia.)

There are several advantages to the use of intraday data and the methodology highlighted above. First, as the timing of intervention can be precisely identified relative to returns, identification problems that arise in lower-frequency data can be avoided.

Second, the factors – such as macroeconomic announcements – that influence returns and consequently the timing and amount of intervention appear to be largely revealed by intraday news, and less so by data at daily or lower frequencies.

Third, the methods used in this paper are also useful for understanding whether the differing goals of intervention, or differences in operating procedures or instruments, appear to influence the effects of intervention. As discussed below, in Latin America, the goals of intervention have varied over time and across central banks. In some cases studied in this paper, the goal has been to dampen exchange rate volatility under an inflation targeting regime (Peru), and in others it has been to adjust foreign reserves for precautionary motives (accumulation in Chile and Colombia, provision of foreign currency in Mexico). As for operating procedures, in three out of the four cases (Chile, Colombia and Mexico) intervention was not discretionary, and auctions offered to purchase or sell predetermined amounts of foreign currency (see below). In the last case (Peru), however, intervention was discretionary and the amounts of foreign currency purchased or sold were not known until after the event.

Nevertheless, at least two caveats may be highlighted. One is that, because interventions in the samples studied in this paper occur over extended periods, intervention days may reflect particular economic or institutional circumstances. This can make it difficult to compare exchange rate behaviour across intervention and non-intervention days, and to consider interventions as events and estimate event study regressions. This is in contrast to G3 interventions, for which the methods used in this paper were first applied, where interventions are far more sporadic, and intervention and non-intervention days are arguably “similar” (with the main difference being the intervention). In this study, this issue is addressed in part by
introducing some controls in the event study regressions (e.g., for US or domestic macroeconomic surprises) and in some cases an indicator of investor sentiment (the VIX) that would capture some factors that could introduce additional systematic differences between intervention and non-intervention days. A more extensive analysis could shed further light on this issue, but is outside the scope of this paper. In Mexico, as discussed below, in one of the cases analysed intervention and non-intervention samples were selected to help make them more similar.\textsuperscript{8}

Another caveat is that this method will not necessarily shed light on the effects of intervention beyond the short intraday intervals considered. However, this topic has been widely studied using daily or quarterly data. The use of confidential intraday data, which is far less common, can shed additional light on the effectiveness of intervention.

II. Data coverage and properties

A. Data description and sources

The analysis in this paper involves three types of high-frequency data: (i) intraday price data for the foreign exchange market from Bloomberg (Peru), Reuters (Mexico) or national sources (Colombia and Chile) – for Colombia, market turnover data are also analysed; (ii) time-stamped US or country (for Colombia and Peru) macro announcements compiled from Bloomberg; and (iii) volume of intervention in the foreign exchange market (see Annex Tables A1 to A3).

1. Intraday price or transactions volume data

The data used in the empirical analysis are time-stamped (transaction) prices in the wholesale spot foreign exchange interbank markets of Chile, Colombia, Mexico and Peru.\textsuperscript{9} For Colombia, time-stamped data on quantities traded are also available. In Chile, all the operations of the central bank are conducted through centralised trading platforms. In Colombia, the data set reflects wholesale spot interbank trades of US currency performed through SET-FX, the centralised interbank foreign exchange electronic market service, which belongs to the Colombian Stock Exchange (BVC). In Mexico, transactions are those reported by Reuters for the Mexican market, but do not include trading of the peso outside Mexico. The Mexican market data are taken as representative because of the size and depth of the peso exchange market and on the assumption that the peso market is globally integrated so no arbitrage opportunities remain. In Peru, foreign exchange trading in the market is done through Datatec and Reuter platforms.

\textsuperscript{8} In particular, the full sample was defined as days on which a USD sales auction was triggered (i.e., Mexican peso depreciated by more than 2%). Intervention days are those on which there was a non-zero allocation, while non-intervention days are those on which there was no allocation even if the auction was triggered.

\textsuperscript{9} In some cases, descriptive statistics are based on bid-ask spreads.

\textsuperscript{10} For more details, see the discussion in García-Verdú and Zerecero (2013).
Construction of the time-series samples used in the paper involved data transformation and the selection of windows that vary from country to country (see also Annex Table A1).

In Chile, the sample covers the episodes of intervention in 2008 and 2011, where the goal was to increase foreign reserves held by the central bank for precautionary reasons. Trade prices in the intraday foreign exchange market are available from 2003. The irregularly-spaced transaction data were transformed into regularly-spaced time interval observations according to the methodology described in Dominguez (1999). The data were arranged in 20-minute time intervals, longer than the five-minute intervals used in Dominguez (1999) because the transactions data were sparse in the earlier years of the sample. The market opens at 8.30 am local time each day and nominally is open till 7 pm. In practice, however, the number of trades drops significantly after 2 pm.

In Colombia, the full sample is from 2 May 2007 to 23 November 2011. Trade prices are marked with the real transaction time to the last second. From these observations, the price on each time mark is calculated as follows. If transactions occur on the time mark, the price at the mark is the average price of these trades. If there are no transactions on the time mark, the price at the mark is the average of the two nearest prices, before and after the time mark, weighted by their corresponding distances to the mark. Data transformations were implemented so as to ensure the most “data gain” (in terms of minimising the interval width in such a way that the upper and lower interval limits reflect actual market activity) while ensuring the quality of the reported data. In particular, the optimal interval width and data loss at the beginning of the trading day were studied carefully.\(^1\) The preceding analysis for the Colombian foreign exchange market resulted in a sample of 1,025 trading days, with 43 prices per trading day (reflecting precise price measurements for each seven-minute time mark from 8.06 am to 1 pm for each trading day), for a total of 44,705 prices.

In Mexico, five-minute price data were used. Following Dominguez (1999), a weighted average of the exchange rate prices closest to the time considered is estimated. The estimation sample goes from 9 October 2008 to 29 November 2011 and it uses data for entire days. There are 215,424 observations in the estimation sample.

In Peru, the sample period (reflecting the span of intervention data available) was from 5 January 2009 to 27 April 2011. Five-minute price data were used. The foreign exchange market in Peru is local and lasts for about four and a half hours, from 9 am to 1.30 pm. Transactions between 9 and 9.15 am are scarce, so the first five-minute interval included in the price data set is 9.15 to 9.20 am. In the five-minute time series, the time index for the business day starts at 9.20 am and ends at

\(^{1}\) For Colombia, it was found that: (i) the first six minutes of the trading day should not be taken into account – this reduces to a minimum the need to carry back the first trading price and conveniently completes the five trading hours so that no data are lost at the end of the trading day; (ii) the optimal interval width is seven minutes, after which the data gain from increasing the width of the time interval decreases; and (iii) days containing too few trades should be deleted. Few trades within a day arise because the market is particularly slow (30 December of any year, for instance) or because of poor record-keeping (price information for whole days or important parts of particular trading days is missing). For consistency, however, the information included was cross-checked with bid/offer quotes and the TRM (Tasa Representativa del Mercado), the official daily exchange rate of the foreign market.
1.30 pm. When calculating the five-minute return series, the returns for 9.20 am are left out.

2. Time-stamped US or country macroeconomic announcements

The empirical analysis reported in this paper includes data on macroeconomic announcements. These are used to construct a set of control variables, and also to compare the relative impact of intervention versus the effects of external macroeconomic announcements compiled from Bloomberg, which are represented by the following US macroeconomic announcements (recorded as surprises; see below): US Consumer Confidence, CPI, Durable Goods, Fed Funds Rate, Unemployment, Housing, Industrial Production, PPI, NAPM, Retail Sales, GDP, and Trade Balance. In some cases, where considered appropriate, data on domestic macroeconomic announcements (eg for Colombia) have also been included as control variables. For more details, see Annex Table A2.

3. Volume of intervention in the foreign exchange market.

The explanatory variable for intervention is constructed by recording the amount of intervention (purchase or sale of foreign currency) at the time it takes place. For the empirical analysis described below, the amounts are expressed in US dollars except for Peru, where they are expressed as a proportion of daily market turnover. For Colombia, the impact of intervention on market turnover is also analysed. The samples for intervention are identified in the next section.

B. Intervention and factors that could influence its impact

1. Transmission channels

What effects might be anticipated from intervention in Latin America in practice? The literature identifies a number of channels through which foreign exchange market intervention could influence the exchange rate, and the effects depend on the way intervention is implemented. The first point to be borne in mind is that foreign exchange operations were sterilised, as all four central banks contributing to this paper adjusted liquidity to meet an interest rate operating target within the framework of inflation targeting regimes. However, foreign exchange market intervention could still have an effect through at least three channels, described below.

To illustrate, consider how central bank (sterilised) purchases of foreign currency could lead to domestic currency depreciation. Under the portfolio balance channel, (sterilised) intervention increases the share of domestic securities in investor portfolios and (assuming domestic and foreign assets are not perfect substitutes) produces an excess supply of such securities which is eliminated by depreciation. The portfolio balance channel could be strengthened if frictions (eg capital controls, transactions taxes, low domestic market liquidity) reduce the substitutability of domestic and foreign assets. In markets with some frictions, the effects of intervention may also be more apparent at very short horizons if the central bank appears to be committed to an exchange rate target, or if intervention

12 These variables have been found to be relevant in influencing the US dollar exchange rate against some major currencies (see Andersen et al (2003)).
is large and unexpected, which may increase the costs associated with rebalancing portfolios.

Under the signalling channel, central bank foreign currency purchases cause an expected easing in future monetary policy, which, by lowering the relative returns on domestic assets, would cause the currency to depreciate. This signalling channel could be particularly relevant in EMEs where intervention is costly (e.g. by imposing quasi-fiscal costs on the central bank when the returns on foreign reserve holdings are below the costs of financing such holdings) and its sustainability may therefore be in doubt unless monetary policy is loosened. However, the relevance of the signalling channel is not always clear: some research has found that rather than signalling a change in monetary policy, intervention can become ineffective if it appears incompatible with monetary policy. In Colombia in the mid-2000s, central bank purchases of foreign exchange tended to dampen exchange rate appreciation when monetary policy was easing, but ceased to be effective when monetary policy tightened, becoming incompatible with the direction of intervention. Part of the problem is that the central bank (which had become a net debtor to the financial system) would find it increasingly costly to drain the liquidity associated with intervention, thus reducing the credibility of such measures (see Kamil (2008) and Vargas (2011)). For further evidence on the signalling channel in Colombia, see Julio and Toro (2005).

Yet another channel is the coordination channel (Taylor (1994), Sarno and Taylor (2001), Reitz and Taylor (2008)). Exchange rates are often thought to be driven by non-fundamental factors which may lead to large and persistent misalignments. In this setting, official foreign exchange market intervention may act as a coordinating signal, encouraging stabilising speculators to re-enter the market at the same time. In Colombia, the coordination channel may have operated around June 2008 when the Colombian peso had appreciated the most relative to June 1999. This situation was an opportunity for the central bank to bring about a depreciation of the peso through forex intervention. Rincón and Toro (2010) find that this was the only period where intervention statistically affected (positively) the exchange rate mean return. Foreign exchange market intervention that tends to “lean against the wind” (seeking to counter the direction of the exchange rate or dampen its volatility) may operate in part through the coordination channel. This channel is likely to be more relevant if central banks target a specific exchange rate level to reduce misalignment.

2. Factors influencing the effects of intervention on the exchange rate

Our review of the channels of transmission of the effects of intervention thus suggests that the effects on the exchange rate would tend to be larger if intervention:

- targeted the exchange rate level or limited volatility to very narrow bands;
- was large relative to market turnover (due to portfolio balance effects) or foreign reserves (possibly also influencing perceptions about monetary policy, owing to quasi-fiscal costs);
- surprised markets.

Targets. In principle, intervention could have a larger impact in the short run if the goal of intervention is to target the level of the exchange rate. This, however
was not the stated objective of the central banks for the periods studied in this paper.\textsuperscript{13} Instead, three of the four central banks explicitly targeted predetermined foreign currency quantities. Thus, the Central Bank of Chile, over the periods 14 April 2008–29 September 2008 and 3 January 2011–16 December 2011, and the Bank of the Republic (Colombia), over three uninterrupted rounds between 24 June 2008 and 30 September 2011, purchased foreign currency to meet preannounced foreign reserve accumulation targets (USD 50 million a day in Chile in 2011 and USD 20 million a day in Colombia). Except for the period September–December 2011, these were, for the most part, periods of capital inflows in Latin American foreign exchange markets.\textsuperscript{14} By contrast, over the period 9 October 2008–9 April 2010,\textsuperscript{15} Mexico sold foreign currency (conducting auctions of dollars with a minimum price), in order to provide the necessary liquidity to counter the conditions of uncertainty and lack of liquidity in the foreign exchange market. The daily amount offered for sale was initially USD 400 million (later USD 300 million) whenever an auction was triggered by a sufficiently large depreciation of the peso (2%). The potential amount that could have been auctioned between 2008 and 2011 was USD 351.06 billion. The intervention sample covers days between 9 October 2008 to April 2010 on which there was a positive allocation of US dollars. There are two non-intervention (control) samples. The first comprises days between 12 April 2010 and 29 November 2011 when there was no intervention whatsoever (“non-intervention sample 1”).\textsuperscript{16} The second covers days during the period from 9 October 2008 to April 2010 on which the intervention mechanism was active but no US dollars were actually allocated during the auctions (“non-intervention sample 2”). Some of the observations in non-intervention sample 2 are selected from days on which US dollars were not allocated in at least one auction. For example, if at 9.30 am US dollars are allocated, and at 11.30 am no dollars are allocated, the 9.30 am observation is part of the intervention sample and the 11.30 am observation is part of non-intervention sample 2. In Mexico, there are 288 observations in the intervention sample, 10,125 in non-intervention sample 1 and 9,295 in non-intervention sample 2. See García-Verdú and Zerecero (2013) for further discussion.

In contrast, foreign exchange market intervention by the Central Reserve Bank of Peru – which was operated by a committee that implements open market operations on a daily basis – was aimed at reducing excess volatility as perceived by the policymakers implementing the intervention. Intervention was fully discretionary in terms of amounts and timing, with markets always aware of the possibility of intervention. Markets only learned the total intervention amount at the end of the day when the figure was made public. Nevertheless, the central bank sought to avoid signalling an exchange rate path (Rossini et al (2013)) while seeking to dampen exchange rate volatility. Over the sample period 5 January 2009–27 April

\textsuperscript{13} In addition, exchange rates may not have served as a signal of future changes in monetary policy, but rather an effort to dampen its effects. For example, one explanation for intervention in Mexico over certain periods (outside the sample studied in this paper) in which the exchange rate faced appreciation pressures related to carry trades is that the central bank could not lower the policy rate to discourage such carry trades because of continued high inflation. See Sidaoui (2012).

\textsuperscript{14} However, intraday exchange rate returns show depreciation over certain time intervals.

\textsuperscript{15} Mexico also sold foreign currency during the period after 30 November 2011, but this is not included because the intraday timing of the auctions changed.

\textsuperscript{16} In Mexico, the period from 30 November to 31 December 2011 is excluded as the type of intervention considered in this paper (with a minimum price (type 3); see García-Verdú and Zerecero (2013)) took place at a different time of day.
2011, there were 7,384 intervention transactions (1,847 in 2009, 5,050 in 2010 and 487 in 2011) and 720 five-minute interval observations (181, 502 and 37 respectively in the same years).

Size of intervention. The intervention studied in this paper occurred in the spot market and was large by some metrics (e.g., compared with interventions in advanced economies prior to the global financial crisis, or compared with foreign reserves) over the sample periods covered in this paper. In Chile, the goal was to increase foreign reserves in 2008 by USD 8 billion (in effect, however, the operation was suspended on 29 September 2008, shortly after the Lehman bankruptcy, having reached USD 5.75 billion). In 2011 the goal was to increase foreign reserves by USD 12 billion through daily purchases of USD 50 million. These totals may be compared with foreign reserves of USD 28 billion at the end of 2010, and interventions of USD 2 billion in 2001. In Colombia, the preannounced interventions were USD 20 million a day in the third round of intervention between September 2010 and September 2011. Over that period, the Bank of the Republic (Colombia) accumulated nearly USD 5.2 billion (compared with foreign reserves of USD 32.4 billion at the end of September 2011). In Mexico, between 9 October 2008 and 9 April 2010, the central bank potentially could have offered a total of USD 351.1 billion, compared with foreign reserves totalling USD 98.28 billion at the end of April 2010. Using another metric, with the exception of Peru, where (discretionary) intervention as a percentage of daily turnover averaged 31% over the sample period, the amount of daily (non-discretionary) intervention compared with market turnover was relatively small, averaging 1.4% in Chile (2011), 2.4% in Colombia (2011) and 0.02% in Mexico.

Market “surprises” and discretion. As discussed later on, there was some scope for “market surprises” at the time the intervention programme was announced. Otherwise, the scope for surprises from intervention was limited in three of the four countries studied in this paper—Chile, Colombia and Mexico—in the sense that the target daily amounts of foreign currency to be purchased or sold over well-defined intervention periods were preannounced. While there was therefore little or no uncertainty about the amounts of foreign currency available for purchase or sale, the actual transaction amounts would depend on the auction procedures. In Colombia, the Bank of the Republic used a three-minute Dutch auction procedure, under which prices could adjust until most if not all of the foreign currency amount targeted was purchased. By contrast, in Mexico, the minimum price procedure implied that the target amount of foreign currency was not sold once the minimum price threshold was reached. In line with this, there were days when no amounts

---

17 The Bank of the Republic accumulated USD 1.4 billion in the first round of intervention ending in October 2008 and USD 1.6 billion in the March–June 2010 intervention round.

18 For a fuller description of this type of foreign exchange market operation in Mexico, see García-Verdú and Zerecero (2013). These sales of foreign currency may at least partly offset large accumulations of foreign reserves from direct foreign currency sales (to meet tax obligations) at the Bank of Mexico by Mexican government institutions, notably the state oil company Pemex. However, as noted by García-Verdú and Zerecero (2013), while the goal of US dollar sales has sometimes been to offset such foreign reserve accumulation, this was not the stated objective during the period considered in this paper.

19 In Colombia, whenever there was a (usually small) residual amount not allotted in the daily auction, it would be carried forward to the next day. Therefore, a slight variation around the USD 20 million target would sometimes be observed during some days of an intervention round.
were allocated even if an auction was triggered (by an overnight depreciation of 2%).

A possibly important source of “surprises” which could strengthen the impact of intervention on exchange rate returns was uncertainty about the timing of intervention during the day. Other than in Mexico, the timing of auctions was not preannounced: for example, in Colombia, sales were announced two minutes in advance. In the case of Peru, intervention could occur on a daily basis at any time during trading hours and contingent on the state of the market (e.g., a substantial drop in the spot price early in the trading day relative to the closing price the day before). The time of intervention during the day (as well as the amount of intervention) was at the discretion of the authorities.

3. Distribution of intervention during the day

In line with the above, the frequency of intervention as well as the target amounts of foreign currency purchased or offered for sale varied over the course of the day in Chile, Colombia and Peru, and to a lesser extent in Mexico.

Graph 1 plots the frequency of intervention and the amount of intervention relative to daily market turnover (intervention in US dollars in the case of Chile) in the course of the trading day. It shows that in Chile most of the foreign exchange operations took place before 1 pm. Only in very exceptional cases did some interventions take place after 3 pm. As explained earlier, trading activity declines significantly after 2 pm, so this explains the clustering of the purchases of foreign currency by the central bank before 1 pm. In Colombia, 76% of the interventions (293 days) occurred between 9.23 and 11.57 am, of which 46% (179 days) occurred between 9.23 and 10.40 am. There was much less intervention (5.7% of the sample or 22 days) earlier in the morning (8.48–8.55 am) or after noon (12.39–12.46 pm). Moreover, interventions at the end of the trading day tend to be more frequent than at the beginning.

By contrast, in Mexico, foreign currency was offered for sale three times a day, at predetermined times (9.30 am, 11.30 am and 1 pm, lasting five minutes each). There were two elements of uncertainty. One is how much would be allocated out of the amount offered in each of the three auctions. As illustrated in the graph, the amounts actually allocated fell, on average, significantly below the amount

---

20 This outcome is used to define a “non-intervention” sample in which the auction is triggered by a sufficiently large depreciation but no foreign currency is allocated.

21 In Colombia, the number of days on which there was an intervention in each M minute interval as a percentage of 387 is reported. In Peru, frequency is computed using the formula $freq_j = \frac{N_j}{J}$, the number of days that have interventions in each M-minute interval of the day (the variable $N_j$ is set to 1 when there is at least one intervention during the jth M-minute interval, and $J$ is the total number of intervals (eg 51 in Peru)), scaled by the total number of interventions summed over all the intervals. The width of the each interval M varied across countries, with $M = 7$ minutes in Colombia, and $M = 5$ minutes in Peru.

22 In Colombia, the distributions (of intervention and control samples) are based on the returns for non-overlapping intervals. The distributions for returns on wider intervals are not shown because whole trading days are missing, which may affect the effective width and thus the returns on these intervals.

23 In a second episode of similar interventions in Mexico starting on 30 November 2011, these times were changed to 9 am, 12 pm and 3 pm respectively. This episode is not included in the analysis.
Another was precisely how much would be offered during each of the three auctions in the day, as the amount would depend on how much was allocated in the earlier auctions. In particular, the amount would be adjusted to ensure that the target daily amount was offered. As illustrated in the graph, on average on intervention days, the amount of foreign currency allocated at auctions as a percentage of market turnover at 9.30 am, 11.30 am and 1 pm was 0.033%, 0.139% and 0.135% respectively.

¹ Based on actual transactions. In Mexico, foreign currency was offered for sale three times a day to total a fixed daily amount. The actual amounts offered in each of the three auctions would vary (subject to their summing to the daily target). The amount allocated also varied. ² Relative frequency, number of days as a percentage of 387.

Source: Central banks.

---

²⁴ In contrast, the amounts offered in the auctions without a minimum price (which sometimes were offered on the same days as auctions with a minimum price) were always fully allocated. See Garcia-Verdú and Zerecero (2013).
In Peru, about 66% of interventions occurred in the last hour of a typical trading day (between 12.25 and 1.30 pm), of which about 63% occurred in the last half an hour, and 15% occurred in the last five minutes.25

C. Descriptive statistics: intraday foreign exchange distribution for whole, intervention and non-intervention samples

A question of interest is whether the differences in approaches to intervention reported above (notably the reliance on discretionary surprise intervention in Peru versus the use of preannounced quantity targets over certain periods in Chile, Colombia and Mexico) are reflected in differences in the impact of intervention on foreign exchange returns and the volatility of such returns.

In order to gain insights into the various effects of intervention, we first explore the distribution of foreign exchange returns over the full, intervention and non-intervention samples.

An important issue is the selection of the non-intervention sample so that it resembles the intervention sample as closely as possible (with the main difference being the intervention). To achieve this, non-intervention samples were chosen spanning periods that were close or adjacent to the intervention periods (see Annex Table A3 for dates selected or criteria used). In the case of Mexico, the non-intervention sample was defined in two ways: (i) days on which a minimum price auction was not triggered; (ii) days on which a minimum price auction was triggered but no US dollars were allocated. In the regression analysis, an attempt to account for remaining differences was made by including control variables.

As shown in Annex Table A4, the distribution of returns over the full sample in Chile, Colombia, Mexico and Peru displays the following characteristics:

- Mean values of returns differ across countries and over time intervals. For example, the exchange rate tends to depreciate (ie changes are positive) in Colombia and Mexico, while tending to appreciate in Chile and Peru.
- Mean and variance of returns increase in absolute value as the time interval increases in Chile, Colombia and Mexico.26 By contrast, in Peru, the mean is the same at the five-minute and 24-hour intervals, and the variance declines as the time interval rises. It may be noted that the size of the variance of returns is much smaller in Peru than in the other three countries studied here.

---

25 Over 124 days, for Peru, two alternative ways of computing the frequency of intervention during trading hours yield different results. The first approach (extensive margin) counts the number of intervention transactions within each five-minute interval across all intervention days. According to this measure (not shown), 53% of all intervention transactions are made in the last 15 minutes of the trading day, of which more than 35% are in the last five minutes. The second approach (intensive margin) divides the sum of intervention volumes at that interval along the whole sample by the number of days that registered interventions at that interval. For example, over the 9.25–9.30 am interval, the sum of the interventions is USD 23 million, which, divided by the two days on which intervention occurred, gives an average of USD 11 million. This measure indicates that the highest intensity of intervention is during the last five-minute interval, and that apart from some peaks (around 10 am, 11 am and 12 pm), the intensity of intervention is more or less uniformly distributed for the remaining intervals.

26 One interpretation is that a higher return is, on average, associated with higher risk.
• *Skewness of returns* is negative at short horizons in Chile, Colombia, Mexico and Peru, but turns positive at longer horizons (ie at longer horizons, the tail of the distribution shifts from the left to the right of the distribution). *Kurtosis* (ie evidence of heavy tails) shows large declines as the time interval increases in all four countries.

The preceding data suggest possible deviations from normality in the behaviour of intraday exchange returns, with skewness away from zero and generally large kurtosis. As noted in Table 1, the Bai and Ng (2005) test was implemented to test whether deviations from normality are statistically significant, with mixed results. In Chile, Colombia, Mexico and Peru, the symmetry of foreign exchange returns could not be rejected, with the sample skewness not significantly different from zero. However, for the full sample, the null hypothesis that kurtosis=3 (implying normality) is generally rejected.

### D. Comparison of intervention and non-intervention days

Further insights may be gained from an informal comparison of intervention and non-intervention days, which suggests the following properties:
• **Mean return.** The currency tends to depreciate during intervention days. During non-intervention days, it tends to depreciate by less or appreciate in Chile, Colombia, Mexico and Peru.\(^\text{27}\)

• **Volatility of returns.** This is higher during intervention days in Chile, Colombia, Mexico and Peru (only at the highest five-minute frequency).

• **Deviations from normality (skewness and kurtosis).** As the Bai and Ng tests suggest that skewness does not deviate from normality,\(^\text{28}\) we focus on kurtosis which tends to be higher on intervention days in Colombia, and lower in Chile and Peru. However, in Peru and Mexico, the Bai and Ng test for kurtosis on five-minute returns (with pre-whitening and degrees of freedom correction) does not reject normality during intervention days, but does on non-intervention days. One interpretation is that discretionary intervention in Peru (and somewhat less precisely, non-discretionary intervention in Mexico) limits the incidence of extreme values.\(^\text{29}\) However, normality is still rejected in Chile and Colombia during intervention days, suggesting that such (non-discretionary) intervention does not eliminate tail risks.

Why are deviations from normality a concern? An important reason is that they could be associated with risks of very sharp movements in the value of portfolios, which in turn can pose financial stability risks. Focusing on heavy tails, a traditional explanation is that they are the result of “irrational behaviour”, such as trend-following. However, recent research also highlights the potential importance of leverage in explaining heavy tails, with possible financial stability implications. For example, Thurner et al (2012) develop a model of leveraged asset purchases with margin calls, with “value investors” and noise traders. Using a line of reasoning that can apply to foreign exchange markets, they show that when funds are not allowed to borrow, asset price fluctuations are approximately normally distributed and uncorrelated across time. However, when leverage is permitted, so that funds can borrow to increase their investments, funds have higher profits during good times, but a downward shock to prices when funds are fully leveraged can lead to margin calls and to sales into already falling markets. This amplifies the downward movement in the asset price and can lead to large losses. This can in turn lead to clustered volatility, in which volatility is low before a crash because value investors are able to dampen volatility, but rises sharply after the crash when they suffer severe losses. Another implication is heavy tails, due to leverage-induced crashes and clustered volatility.\(^\text{30}\)

---

\(^{27}\) While the very high-frequency data show no trend in Peru: when the central bank intervened, the exchange rate tended to appreciate; and when the central bank did not intervene, the exchange rate tended to depreciate.

\(^{28}\) Skewness generally becomes negative for intervention days in Colombia, Mexico and Peru. In Mexico, skewness on intervention days is mixed (positive at five-minute and 24-hour intervals, negative in between). It is positive on type 1 non-intervention days, and negative on type 2 non-intervention days. In Peru, skewness is positive at most frequencies on intervention days, while the sign switches on non-intervention days.

\(^{29}\) To put it differently, this might mean that during non-intervention days relatively more extreme exchange rate movements have been allowed, for example sharp (extreme) depreciation on non-intervention day \(t\) following a series of high (but not extreme) appreciations on intervention day \(t-1\).

\(^{30}\) As for (negative) skewness, it is potentially a concern because it could also indicate crash risks. In an empirical study of eight major currencies’ exchange rates relative to the US dollar, Brunnermeier et al (2009) find that countries with high interest rate differentials (ie destination or investment
E. Average return volatility for intervention and non-intervention days

Following Dominguez (2003), samples of intervention and non-intervention time windows were matched according to the time of intervention and the day of the week. The idea is to control for volatility seasonality by day of the week as well as intraday.

For Chile, Graph 2 (top left-hand panel) shows the standard deviations of returns for the 2011 and 2008 interventions, with the red line for the intervention sample and the blue line for the counterfactual. Volatility declines during the day, but more steeply during non-intervention days.

In Colombia, the volatility tends to increase slightly 7 to 14 minutes before the intervention, and the duration of this increase lasts until impact, to return very quickly to the volatility of the control sample. However, a slight volatility spike may also be observed 35 minutes after the intervention.31

For Mexico, average return volatility for intervention and non-intervention days was examined at 9.30 am, 11.30 am and 1 pm using transaction data. It was found that: (i) average return volatility on intervention days is on average greater than on non-intervention days; and (ii) the average return volatility for intervention days is much higher at 9.30 am than at 11.30 am and 1 pm, spiking approximately 15 minutes after intervention. These graphs are not shown.

In Peru, the distribution of intervention during the day has a bearing on the volatility comparisons. As noted, intervention tends to cluster late in the trading day: in 48 out of 124 days with intervention operations, interventions clustered in the last half-hour (ie with no intervention in the two hours prior to the cluster, from 11 am to 1 pm; or during the early hours of the next trading day, from 9.25 to 11 am).

A question of interest (see Dominguez (2003)) is whether volatility is affected by intervention before or after it takes place. For this purpose, non-overlapping intervention episodes need to be identified. This is particularly challenging in the case of Peru, because intervention occurs at all times during the trading day and most notably in the last half-hour of trading. To deal with this, an effort was made to (i) isolate intervention clusters during the last half-hour of trading; and (ii) assuming that the foreign exchange market has no interruptions between 1.30 pm and 2.30 pm, tend to have negative skewness, implying that carry trade returns have crash risks. The reverse would be true for funding currencies. As a possible explanation, Brunnermeier and Pedersen (2009) show – in a setting where agents are liquidity constrained – that securities which speculators invest in have a positive average return (a reward for providing liquidity) and a negative skewness (because shocks that lead to speculator losses are amplified when speculators hit funding constraints and unwind their positions, while shocks that lead to speculator gains are not amplified).

31 For Colombia, a disaggregated comparison of mean square returns between the control and intervention matched samples is available from Juan Manuel Julio and Hernán Rincón. It suggests that the response of mean square returns to intervention is not homogenous, varying with the time and day of the week of the intervention. However, on average, the mean square of seven-minute returns tends to increase slightly 7 to 14 minutes before the intervention and spikes on impact to return very quickly to the level of volatility of the control sample. However, this type of analysis does not rule out longer-term effects on volatility. Aggregate results for Colombia are shown in Graph 2. Assuming there is no intraday seasonality, all the intervention and non-intervention samples may be pooled to observe the average relationship between the volatility of returns and intervention over the sample.
and 9.25 am the following day. The variance of returns (as measured by squared returns) can then be measured before, during and after the intervention cluster.

1 Standard deviation of 20-minute returns. 2 Volatility comparison around intervention cluster.

Source: Central banks.

As shown in Graph 2, there is a peak in volatility at 1 pm, just when the intervention cluster starts. Volatility falls after the peak and during the central bank intervention and remains low during the first two trading hours of the next day. Volatility also tends to be higher before the intervention cluster as compared with the control sample, which includes matched (by time of day and day of week) five-minute volatility observations during non-intervention days. A striking outcome of this analysis is that it shows that volatility in the early hours of the day following intervention remains low compared with the volatility of non-intervention days.

Intervention and non-intervention samples can be compared assuming that news, shocks and policy events that occur after the market closes at 1.30 pm are not related to an intervention that took place in the morning. For example, the central bank announces its interest rate policy decision in the evening of a given Thursday.
each month. The assumption here is that the policy rate decision is orthogonal to the intervention decision.

F. The Brown-Forsythe homoscedasticity test

To test for differences in the volatility of returns before and after an intervention operation (homoscedasticity), the Brown-Forsythe test was conducted. For Mexico and Peru, tests of homoscedasticity during the day were conducted. In the case of Mexico, the test is whether variances were equal in a symmetric way around the time of the three interventions for all samples (the window is 20 minutes before and 20 minutes after intervention). As shown in Table 2, the null hypothesis of equal variances is not rejected. However, given the reduced size of the intervention sample, the test is not conclusive.

In the case of Peru, given the presence of intervention clusters, the first test was to check whether the volatility of returns differs before and after the intervention cluster, for both the intervention and non-intervention (control) samples at five-minute intervals. The null hypothesis of equal variances (that the sample variances are homoscedastic) before and after 11 am is rejected for both the intervention (F-statistic 4.59, p-value 4%) and the non-intervention (F-statistic 13.48, p-value 0.06%) samples. Similar results were obtained with a second exercise, which was performed with volatilities around isolated intervention events (not preceded by any intervention event two hours before or after) that occur within five-minute intervals during the day. This type of event is relatively rare in the Peruvian market (only 28 cases are documented) but is closest in spirit to the one performed in Dominguez (2003) because it focuses on event time and not clock time.

---

32 Homoscedasticity at different times of day was also tested using Colombian data. The findings suggest that for particular times of intervention – but not for others – there is strong evidence of heteroscedasticity.
The Brown-Forsythe test (Table 2) was in some cases also implemented to test for homoscedasticity between the pooled intervention and non-intervention samples. In Chile and Colombia, the value of the statistic is 19.07 and 27.06 respectively, so homoscedasticity is rejected at the 1% significance level. While volatility of returns (seven minutes in the case of Colombia) thus differs between the intervention and non-intervention samples, this result might not hold for all intervention times in the sample. \(^{33}\)

In Chile, this result might be explained by the fact that the foreign exchange interventions, especially the 2008 episode, tend to coincide with periods of distress in international capital markets. Indeed, as noted earlier, the declared intention was to accumulate foreign exchange in order to be better prepared to face periods of turmoil.

G. Volatility seasonal

Following Dominguez (2006), the intraday seasonal component of the volatility of returns was estimated for Chile, Colombia, Mexico and Peru.

In the case of Colombia, an ARCH(2) model with $\text{T}$ distributed residuals was fitted to the 1,025 average daily returns. From this model, the daily volatility factor $\sigma_t$ was estimated for each day $t$ in the sample. \(^{34}\) By estimating $E[R_{w,i}]$ with the sample mean return over the sample, the estimate of $x_{w,i}$ in Dominguez (2006, equation 6, p 1,057) was computed for each intraday sub-interval $n$ and day $i$, where $N = 42$ is the number of intraday intervals in the trading day. A tuning parameter $p=5$ was selected after comparing estimated volatility seasonals for tuning parameters between 4 and 9 (evidence of overfitting at the end of trading was found for $p > 6$, and of underfitting for $p < 4$, with the results basically the same for $p$ between 4 and 6).

For Chile and Mexico, the seasonal component was estimated first by using non-intervention days, and then by considering the whole sample, the underlying assumption being that the seasonal component does not change through the sample. A GARCH model (instead of a FIGARCH) was used, with parameter $p=6$.

For Peru, the average of squared returns was calculated for each five-minute interval over the full intervention and non-intervention samples. To estimate the smooth seasonal component (see Dominguez (2006)), an MA(1)=FIGARCH(1,d,1) model for daily returns was fitted to the 5 January 2009 to 27 April 2011 sample. This makes it possible to estimate the daily volatility factor $\sigma_t$, which is then used in the flexible Fourier form (FFF) regression (Dominguez (2006, p 1,057)). The tuning parameter for estimating the volatility seasonal is $p=7$.

\(^{33}\) For Colombia, the $p$-value of the test for homoscedasticity between the pooled intervention and non-intervention samples at the most frequent times of intervention were also obtained and suggest that at the time of intervention – but not at other times – there is strong evidence of heteroscedasticity. The results are available from Juan Manuel Julio and Hernán Rincón.

\(^{34}\) Alternative ARCH and GARCH specifications were tried, and GARCH terms did not significantly affect the volatility of mean daily returns.
Graph 3 shows the volatility estimates on the pooled intervention and non-intervention samples, as well as the volatility seasonal calculated as in Dominguez (2006)\(^{35}\). In Chile and Colombia, except for a normalisation constant, the volatility seasonal picks up the features of intraday volatility. On an average trading day, the volatility of returns starts high and falls slowly. A similar pattern is observed in Peru, where in both intervention and non-intervention samples, volatilities tend to be higher during the early hours of a trading day. The estimated volatility seasonal is high around 10.10 am, 11 am and at the close of the trading day. From 10.30 am to 1 pm, the volatility for intervention days is higher than the volatility during the non-intervention days. After 1 pm, both volatilities tend to be the same. The pattern is quite different in Mexico, where trading in the peso takes place over a 24-hour period. The volatility seasonal rises until about 1 pm, is relatively stable until about 7 pm and then declines.

\(^{35}\)Dominguez (2006, equation (8), p 1,058).

\(^{1}\) Forty-minute windows around 9.30 am, 11.30 am and 1.30 pm interventions.

Source: Central banks.
One interpretation of these results is that the volatility seasonal declines as the market agrees on the effect of exogenous information on prices. However, in Colombia and Peru, the explanation for higher volatility at the end of the trading day is less clear because trades are less frequent in Colombia, but more frequent in Peru (see Graph 1).

III. Empirical analysis

A. Event study regression

Following Dominguez (2003, 2006), a set of regressions was estimated to study the effect of foreign exchange market intervention on the mean return, return volatility and (for Colombia) market turnover. Further details are available from the respective central bank co-authors.

The following specifications are reported in this paper:

- regression of mean return on dummy variables for intervention and control variables (typically macroeconomic surprises);
- regression of the volatility of returns on intervention and control variables;
- regression of market turnover on intervention and control variables and intraday seasonals (Colombia only).

The general specification used was as follows:

**Event style regression with macroeconomic/announcement control variables**

**Returns regression**

\[
R_{t,i+l} = \beta_0 + \sum_{l=-m^L}^{m^L} \beta_{1,i+l} I_{t,i+l} + \sum_{j=1}^{n} \sum_{l=-m^K}^{m^K} \beta_{2,i+l} K^j_{t,i+l} + \sum_{k=1}^{p^R} \beta_{3,i+l-k} R_{t,i+l-k} + \epsilon_{t,i+l}
\]

**Volatility regression**

\[
V_{t,i+l} = \gamma_0 + \sum_{l=-m^L}^{m^L} \gamma_{1,i+l} I_{t,i+l} + \sum_{j=1}^{n} \sum_{l=-m^K}^{m^K} \gamma_{2,i+l} K^j_{t,i+l} + \sum_{k=1}^{p^V} \gamma_{3,i+l-k} V_{t,i+l-k} + \gamma_4 S_{t,i+l} + \phi_{t,i+l}
\]

**Turnover regression (Colombia)**

\[
T_{t,i+l} = \delta_0 + \sum_{l=-m^L}^{m^L} \delta_{1,i+l} I_{t,i+l} + \sum_{j=1}^{n} \sum_{l=-m^K}^{m^K} \delta_{2,i+l} K^j_{t,i+l} + \sum_{k=1}^{p^T} \delta_{3,i+l-k} T_{t,i+l-k} + \delta_4 S_{t,i+l} + \epsilon_{t,i+l}
\]

36 For Colombia, the general equation specification for the effect of the intervention on the mean return and turnover follows Dominguez (2003, equation (1), page 34), and the equation to study the effect of intervention on the mean volatility of returns follows Dominguez (2006, equation 9, page 1059).

37 As a reference, see Dominguez (2003, 2006), who implements similar regressions using US data.
\[ R = \text{exchange rate returns} \]
\[ V = \text{volatility of returns (absolute value of returns for Colombia and Peru, standard deviation for Mexico and Chile)} \]
\[ I = \text{intervention in US dollars (for Peru as a proportion of market turnover)} \]
\[ K = \text{control variables indexed by } j = 1 \text{ to } n. \text{ The baseline specification includes 12 US macroeconomic surprises (defined below), expressed in absolute values in the volatility and turnover regressions.} \]
\[ S = \text{intraday seasonal} \]
\[ T = \text{market turnover} \]
\[ t = \text{intervention date} \]
\[ i = \text{time of intervention} \]
\[ j = \text{types of announcements (1 to } n) \]
\[ l = \text{leads and lags (ranging from } -m \text{ to } m \text{) for intervention and announcements} \]
\[ k = \text{lags on the dependent variable (1 to } p). \text{ The number of lags was selected by information criteria in a number of countries (eg for Colombia } p=3 \text{ by the Schwartz criterion and for Peru } p=6 \text{ by the Akaike criterion). In Chile, given that the sample was divided into 20-minute intervals, the interventions took place mostly in the earlier part of trading activity, which declines significantly after 1 pm. A constant number of three leads and lags was chosen for every variable.} \]

The superscripts for the total number of lags, \( n, m \) or \( p \), refer to the corresponding regression to which they apply. Estimation was implemented using alternative methods, ie GMM for Colombia and Mexico, HAC (Newey-West robust standard errors) for Peru and OLS for Chile.

In the above specifications:

- intraday returns data are only those recorded on the days on which the central bank intervened;
- significant lead coefficients on intervention would suggest market participants know about the interventions before they took place;
- it is possible to test for intraday persistence or mean reversion by checking whether the lag coefficients sum to zero.

**Variable specification**

Before reporting the regression results, it is useful to describe how the variables are specified, and the window around which estimation was performed.

**Intervention leads and lags**

In general, if an intervention takes place on day \( t \) at time \( i \), the lag and lead with respect to the intervention time is set at \( l \). Then the intervention amount \( I_{i,t+l} \) is entered at the time of intervention\(^{38}\) and for a symmetric time window of a

\(^{38}\) In earlier versions of this paper, intervention dummies were used as explanatory variables instead of intervention amounts. For some countries with a fixed amount of daily intervention (eg Colombia) the results using intervention dummies were similar to those using intervention quantities.
prespecified length (from \(-m^t\) to \(m^t\)) before and after the intervention. The intervention amount is set to zero if there was no intervention on day \(t\). The coefficients \(\beta_{1,t+1}\) are thus associated to the time before, at and after the intervention. These are the coefficients that are plotted in Graph 4, along with the associated two standard error bands.

In Colombia, after fitting several models with windows as wide as two hours before and after the intervention for the leads and lags of the intervention and news indicators, a symmetric window of 70 minutes that contained each intervention was chosen. In line with this choice, the intervention occurs at some point between time marks 00:35 and 00:42 and its effect on any of the three variables is estimated on a time window consisting of 35 minutes before and 35 minutes after the intervention (in Colombia, the value of \(m^t = 35\)).

Moreover, an analysis of the frequency of news releases in windows around interventions reveals that there are just 23 news releases (observations) in a 70-minute window around interventions, only 15 in a 42-minute window, and only one on impact (in a seven-minute interval). In addition, a closer look at these releases shows that there is no concentration of interventions near to announcements of any particular macro indicator. Therefore, for Colombia, there does not seem to be enough sample information to study the effect of the interaction between intervention and the macro announcements of particular variables.

For Chile, all trading activity for each day was considered. Since interventions tend to occur in the early part of the trading hours, the number of observations for the leads of this variable is not constant in all the days considered. This may introduce bias when evaluating the lead or anticipated effect of the interventions.

In the case of Mexico, interventions occur only three times a day, rather than continuously throughout the day. The intervention variables are specified by setting a symmetric time window of 40 minutes on intervention day \(t\) at the time of intervention (i.e., either 9.30 am, 11.30 am or 1 pm). In Mexico, the value of \(m^t = 20\).

For Peru, leads and lags were chosen to maximise the \(p\)-value of the Wald statistic for the null hypothesis that all coefficients are jointly equal to zero.

Control variables

External surprises and indicators. The regressions also include control variables, notably a set of macroeconomic news announcements, which are included in the form of surprises (for more details on the series included, see Annex Table A2). Surprises are defined as the difference between the macroeconomic announcement and the median expectations (as indicated by survey forecasts taken from Bloomberg), standardised by the standard deviation of the survey. For Mexico and Peru, however, the standard deviation is approximated by the difference of the maximum minus the minimum divided by six.\(^{39}\)

However, in countries where the amount of intervention was discretionary during the sample period (Peru) or depended on auction results (Mexico), the results would differ.

\(^{39}\) In Mexico, positive news announcements are defined as realized values for the variable in question above the median plus the standard deviation. Negative news announcements are defined as a realized value for the variable in question below the median minus the standard deviation. See Garcia-Verdu and Zerecero (2013).
In the regressions for Chile, Colombia, Mexico and Peru, 12 types of US macroeconomic announcements (listed earlier) were included, denoted by \( j = 1, \ldots, 12 \). However, the results for only some of the macroeconomic announcements are reported for Mexico. In the cases in which the returns are the dependent variable, for the estimation of the partial sums (and not for the regressions) only the variables for which the effect on the exchange rate was not ambiguous in the short run were included. In particular, news announcements that led to an appreciation in the exchange rate were included, while coefficients for unemployment, the federal funds rate and the trade balance are not included because interpretation of the expected sign on returns in reaction to these surprises is ambiguous.

Absolute macroeconomic surprise announcements were used on the right-hand side in the volatility (Chile, Colombia, Mexico and Peru) and turnover (Colombia) equations. In addition, the daily VIX was included.

Other controls. In addition to these controls, in the specifications for Colombia, three domestic surprises are included as well as a daily implied tax on capital flows. For Mexico, a dummy variable is included as a control when auctions with no minimum price were implemented during the same days as auctions without a minimum price (the focus of the present paper). For Peru, a dummy variable is included that controls for the first interval within an hour.

Span of intraday data. For Mexico, since many news announcements’ time stamps are earlier than 9:10 am, the intervals of the days were extended accordingly. For example, if there is a news announcement at 7:30 am, data starting at 7:10 am is considered (data can go from 7:10 am to 2:35 pm, as 7:30 am is the earliest time and 2:15 pm is the latest time news announcements take place in the Mexican database).

For the intervention and announcement series, observations outside the windows on intervention days are not included. No-intervention days are also excluded.

Lag selection for control variables. For Peru the span of the leads and lags on surprises was selected to minimise an information criterion (AIC) and test the joint significance of the coefficients using Wald tests. For intervention, leads and lags ranged from -6 to 6 (ie \( m = 6 \)); for the dummy variable controlling the first interval in the hour, the lead and lag ranged from -1 to 1.

### B. Impact of intervention on mean returns and volatility

1. The effect of the intervention on mean returns

Graph 4, left column, shows the estimated coefficients of leading, contemporary and lagged intervention.

For Chile, the first row of Graph 4 shows that 2 periods before the intervention, returns show a significant appreciation. However the point estimates shift to depreciation and become insignificant closer to the time of intervention and after it.
The effects of intervention on mean returns (lead and lag coefficients within intervention window)

In basis points unless otherwise indicated

Graph 4

Chile

Colombia

Mexico

1

2

3

4
In the case of Colombia, the second row of Graph 4 illustrates the impact of an USD 1 million intervention – measured in basis points – on 7-minute mean returns of the COP/USD exchange rate. Turning to the left hand panel, the solid line corresponds to the coefficient estimates, while the dashed lines show two standard deviation confidence intervals derived from a GMM estimation procedure. The graph shows a small (0.14 basis points), significant increase in mean returns on impact. After reversing (with some overshooting) the effect is zero 1:03-00:42 minutes after the intervention. Moreover, the cumulative effect of intervention (column 2) is not significant.

For Mexico, the effects on returns of intervention in the form of minimum price auctions are not significant.

In the case of Peru, the right hand panel shows the cumulative response of returns before and after a purchase intervention equivalent to 10 per cent of turnover (approximately 1 standard deviation of historical intervention amounts relative to turnover), in a regression that takes into account controls in the form of US macroeconomic surprises. The effect on cumulative returns is close to 0.03 per cent for about 30 minutes (by way of comparison, the effect in a regression with no controls is about 0.01 per cent). For example, if the initial spot price is 2.700 soles, it increases up to about 2.7008 soles within the first minutes after the intervention (ie about 8 pips\textsuperscript{40}). However, no long-run effect of intervention on returns was detected.

\textsuperscript{40} Compared to 0.04 pips in a regression with no controls A pip is the smallest unit of price for any foreign currency. The USD-PEN currency is quoted with 4 decimal points.
2. The effects of surprise US announcements on mean returns

As noted earlier, US macroeconomic surprises were added as controls. A question of interest is whether the effect of such announcements are large compared to the effects of intervention. If they are, policymakers may see a need to intervene more actively, or to accumulate larger amounts of foreign reserves in order to respond to external shocks.

For the Chilean case several US macroeconomic surprises were included as controls in the regression. For exposition purposes only the effect of the GDP announcements are shown in Graph 5. As can be seen the effect is not significant from a statistical point of view although it has the positive sign (i.e., a US GDP increase is associated with a depreciation in the Chilean peso) that economic theory predicts. In terms of economic significance the effect is much larger than is estimated for interventions. This suggests that foreign macroeconomic news have a relevant effect on the Chilean peso return although the magnitude can’t be estimated precisely.

In the case of Colombia, the market reacted to a positive surprise to US consumer confidence in anticipation and with a lag. This shock lowers the seven-minute mean return by around 8 basis points on impact. Moreover, the confidence bands suggest that there are also borderline significant leading effects, as well as significant lagged effects on average returns. The cumulative effect on mean returns of a standard deviation surprise US macroeconomic announcement (represented by US consumer confidence in Colombia) is negative and significant after the impact, lasting around 15 minutes. However, the effect reverts to zero thereafter. The effects of other US macro surprises showed similar characteristics.

In the case of Mexico, news announcements have, in absolute magnitude, a much greater effect than intervention. However, there is a clear “regress to the mean” effect on returns after the news announcements.

In the case of Peru, a positive US macro surprise reduces returns. The effect seems to be permanent in the case of surprises to either GDP or retail sales.

On average, the responses of mean returns to a positive average US surprise (e.g., US consumer confidence) are much larger than the effect of the intervention, particularly on impact in Colombia, Mexico and Peru (almost twice the effect of the approximately 1 standard deviation shock of intervention to turnover). One explanation is that macroeconomic surprises – unlike intervention – are usually related to fundamentals.

---

41 The estimated effect of any other macroeconomic surprise may be requested from Hernan Rincon and Juan Manuel Julio, Bank of the Republic (Colombia).

42 The estimation of the effect of Colombian macroeconomic announcements is more involved as these observations tend to be off market hours, and were therefore carried forward to the 8:06 minutes time mark of the following trading day. The coefficient estimates related to these announcements may be biased and thus are not shown here.
The effects of surprise US announcements on mean returns (lead and lag coefficients within intervention window)

In basis points unless otherwise indicated

Graph 5

Chile

Colombia (US consumer confidence)

Mexico (to be fixed)
3. The effects of intervention and macro announcements on the volatility of returns

In this section, the effects of intervention and macro announcements on the intraday volatility of returns are discussed. Following the specification shown in Table 2, the endogenous variable is the absolute value of returns. Intervention volumes (in Peru, as a fraction of daily turnover) and macroeconomic surprises are entered as explanatory variables, as is the intraday seasonal corresponding to the period of time within the day (for Colombia, the intraday seasonal was also added to the turnover equation). Graph 6 shows the estimated coefficients on intervention (left-hand panels) and on macroeconomic surprises.

a. The effects of intervention on the volatility of returns

In Chile and Mexico, intervention appears to have no significant effect on volatility during the window considered. In Colombia the (seven-minute) volatility of returns falls 25 and 21 minutes before the intervention auction is announced. Beyond this, intervention does not seem to modify the volatility during or after the intervention, except perhaps for a slight reduction seven minutes after the intervention.

In Mexico, when using intervention quantities, there seems to be an increase in volatility minutes after the intervention takes place, and in some specifications a positive and statistically significant effect 20 minutes after the intervention. However, the effects do not appear to be economically significant.\(^43\) On the other

---

\(^43\) For example the average transaction variance for the intervention sample is 1.202E-05, while the maximum estimate of the coefficients associated with intervention in the regressions when using the quantities for the interventions and standardized announcement is below 1E-5, i.e. a 0.0043 relative effect.
hand, when dummies are used for interventions and macroeconomic announcements (not shown), the effects are economically significant. One reason may be that dummies mitigate simultaneity that arises because there is a trigger mechanism for the auction, which depends on the exchange rate. Thus, there is some indication that volatility might increase after the intervention. Also, the Bank of Mexico authors performed GMM-SUR estimations separating the actual time of the intervention and found that at 9 am the effects tend to be much stronger.

In Peru, the response to an intervention equivalent to 10% of turnover is shown. Volatility, measured as the absolute value of returns, increases contemporaneously and five minutes after intervention, falling 10 minutes after intervention. However, these effects are not statistically significant. Nevertheless, a correlation may not be apparent if the large presence of the central bank in the foreign exchange market (30% of market turnover on average) successfully reduces volatility to very low levels by deterring market participants from taking positions that are counter to those of the central bank. Volatility in Peru’s foreign exchange returns is much lower than in the other countries studied in this paper (see Annex Table A4).

b. The effects of US macroeconomic announcements on the volatility of returns

In Mexico, surprise US news announcements have, in absolute magnitude, a much greater effect on volatility than do intervention. The effects are significant at certain points in time. In Colombia, a surprise to US consumer confidence has no effect on the volatility of returns on impact, but reduces the seven-minute returns volatility 7 and 28 minutes later. Moreover, volatility increases significantly 21 minutes prior to the intervention. However, the volatility before the announcement tends to be higher than the volatility immediately after the announcement. In Mexico, the reverse appears to be true.

For Peru, the effects of US announcements are large, statistically significant, and persistent.

The effects of intervention and surprise US announcements on the volatility of returns (lead and lag coefficients)
4. Effects of intervention and US announcements on market turnover (Colombia)

A novel feature of the Colombian data set is that the volume of each trade is recorded, which makes it possible to calculate market turnover for any set of intraday intervals of time. Therefore, the effect of the intervention on market
turnover may be assessed using an event study regression similar to that in Dominguez (1999, 2003, 2006).

What effect would we expect intervention to have on market turnover? The literature suggests that if intervention results in more market agreement on the exchange rate, market turnover should fall (Jorion (1996), Tauchen and Pitts (1983)). Furthermore, volatility should also fall, as a large body of evidence suggests that (detrended) volume is positively related to volatility.

However, Colombia was not targeting the exchange rate over the sample period, so it is not clear ex ante whether more agreement on the exchange rate and lower market turnover should be expected. On the one hand, the regular purchases of foreign currency might have increased agreement that appreciation pressures would be dampened, reducing market turnover and volatility. In line with this, the regression results reported earlier indicate that a USD 20 million intervention significantly increases mean returns by 2.8 basis points on impact, and reduces mean returns by 1.17 basis points seven minutes after the intervention. The exchange rate thus increases permanently by 1.63 basis points after the intervention.

On the other hand, by improving resilience to external shocks, foreign currency purchases could also contribute to sharper appreciation and one-sided behaviour. In a setting in which appreciation pressures are already significant, market turnover and volatility could increase further.

Source: Central banks.

Graph 7 shows that in Colombia during the sample period, market turnover increased by USD 4 million seven minutes before the intervention and USD 20 million on impact. It then fell sharply. One interpretation is that disagreement rises prior to intervention and falls after it. In line with this interpretation, the coefficients of volatility in exchange rate returns rise before the intervention, also peaking seven minutes before the intervention, and then fall at the time of intervention and later (volatility rises again some time after the
intervention; see Graph 7). The implication is that intervention might increase agreement about exchange rates in the market, at least temporarily.

Further insights on the drivers of market turnover are provided by the responses to the other explanatory variables.

- A 1 standard deviation US consumer confidence surprise is associated with a sharp increase in turnover on impact, with a much larger effect on turnover than that of daily intervention. The increase in turnover is later partly reversed.
- The effect of the VIX on market turnover is small, negative and very significant, much like the effect of the implied tax of capital controls.
- The coefficients related to lags of turnover reveal moderate turnover persistence. High persistence in turnover is likely to be related to the persistence of the intraday market turnover seasonal.

5. Effects of intervention announcements on exchange rate expectations (Chile)

Earlier in this paper, we conducted several empirical exercises to determine the impact of intervention on intraday exchange rate returns and their volatility.

In doing so, we implicitly assumed that the effects of intervention are well captured by considering days on which dollar purchases or sales take place. However, in the case of preannounced interventions (applying to three of the four countries in this paper), there may also be effects when the interventions are announced as well as from the subsequent actual dollar purchases or sales. This distinction is important as the “surprise” effect of the intervention, if any, might not be well captured during “purchase (or sale) days” when there is a long enough time window between the intervention announcement and the corresponding foreign exchange market operations.

To illustrate the impact of announcements on the exchange rate, we consider the experience of Chile when the intervention programmes of 2008 and 2011 (ie those examined in the preceding empirical analysis) were announced. The announcements were as follows:

- 10 April 2008: a Central Bank of Chile press release issued between 7.15 and 7.45 pm announced the start of a dollar purchase programme on 14 April 2008. The release stated that a total of USD 8,000 million would be purchased daily at a rate of USD50 million on every day.
- 29 September 29th 2008: a Central Bank of Chile press release between 5:40 PM and 5:48 PM announced the immediate cessation of the intervention program announced on April 10th 2008. Dollar purchases were discontinued right after this announcement. The release stated that this decision was made in order to mitigate the consequences that the global financial turmoil may have on the Chilean economy.
- 3 January 2011: a Central Bank of Chile press release published at 6 PM announced a dollar purchase programme starting on 5 January 2011. The release stated that a total of US$12000 million would be purchased daily at a rate of US$50 million a day.

Graph 8 shows the level of the peso-dollar parity around the time of these three announcements.
Graph 8 shows that shortly after these announcements (left hand and center panels) the level of the exchange rate experienced a substantial shift. In April 2008 the Chilean peso depreciated against the US dollar by 1.99% in either the first or second transaction recorded after the announcement. In January 2011 the Chilean peso depreciated by 3.14% in the second transaction recorded after the announcement. The announcement of the early termination of US dollar purchases in September 2008 also appears to have had a visible effect: the Chilean peso appreciated 2.04% in the first transaction after the announcement.

Was the behaviour of returns particularly unusual around the time of intervention-related announcements? To shed light on this, we look at the empirical distribution of short term foreign exchange returns from 2007 to 2011. This histogram is depicted in Graph 9 and is constructed using more than 100,000 observations.

We find that less than 0.01% of the available short term returns are as high or higher than the returns obtained in either the first or second transactions after the announcements associated with the start of an intervention program. Similarly, less than 0.01% of the short term returns recorded are lower than the -2.04% return obtained right after the 2008 intervention was stopped.

---

1 Observations are taken every 5 minutes; the scale of the X axis represents days. 2 From 20 March 2008 to 9 May 2008. 3 From 15 December 2010 to 21 January 2011. 4 From 8 September 2008 to 17 October 2008. 5 Announcements made on 10 April 2008 (Time 19:15-19:45) and 3 January 2011 (Time 18:00); equals value 0 on x-axis. 6 Programs of dollar purchases began on 14 April 2008 and 5 January 2011. 7 The intervention is stopped at 29 September 2008 (Time 17:40-17:48); equals value 0 on x-axis.

Source: Central banks

---

These short-term returns are calculated according to the representative price of the currency following the methodology in Dominguez (1999). Most of the short-term returns correspond to five-minute returns. Nevertheless, we also consider in our analysis slightly longer returns when no transactions are recorded during a five-minute window. We also include in our data the open-close return. In summary, our data are heterogeneous, but they share the common feature of being either five-minute returns or the shortest available exchange rate returns when no transactions are recorded during a five-minute window.
To sum up, the behaviour of short term exchange rate returns is extremely unusual in the first transactions after intervention announcements, and suggests that these intervention programs had a substantial impact on short term exchange rate returns in Chile.

This discussion implies that – because they do not take into account the announcement effects – the empirical results on the effects of the actual foreign exchange market operations of central banks reported previously may understate the impact of foreign exchange market intervention on the exchange rate. As illustrated by the experience of Chile, the announcement effects can be large and lead to a significant shift in the level of the exchange rate. In line with this, intervention is also associated with unusual behavior in exchange rate returns.

Conclusions

Central banks have intervened for extended periods in foreign exchange markets in Latin America for significant amounts (from less than 2.5% of market turnover in Chile, Colombia and Mexico to over 30% of market turnover in Peru). Intervention may pose challenges for monetary policy implementation and impose quasi-fiscal costs (purchases of foreign assets generally yield lower returns than the debt sold to finance such purchases). They also raise questions about effectiveness.

The analysis of intervention using intraday data in (four) Latin American countries yields the following results.

First, high frequency intraday exchange returns are characterised by deviations from normality. In particular, returns exhibit heavy tails (high kurtosis) on no-intervention days but in a number of cases do not deviate from normality on intervention days. A question of interest is how these results may be interpreted, and the possible implications, given that there is a literature that suggests that heavy tails could reflect the risk of sudden crashes due to leverage.

Second, the evidence from Chile, Colombia and Mexico on sterilised, rule-based intervention that targets purchases/sales of preannounced quantities of foreign reserves is that the actual transactions have at times significant but transitory effects on foreign exchange returns. The effects of such transactions on exchange rate
volatility are also transitory. Also for rules-based interventions, the effects of intervention transactions on exchange rate returns and volatility appear to be smaller than the effects of US macroeconomic policy announcements, but such announcements also appear to have transitory effects. One implication is that sterilised, rule-based intervention transactions intended to accumulate foreign reserves or to increase liquidity do not significantly distort the price discovery mechanism in the foreign exchange market. This view is supported by data suggesting that the size of the intervention transactions relative to market turnover is not very large. Another implication however is that to counter large shocks to the exchange rate would probably require large intervention transactions.

Third, the effects on foreign exchange returns of preannounced, non-discretionary intervention transactions must be distinguished from the effects of intervention announcements. The data presented in this paper on the experience of Chile suggests that these effects can be significant, highly persistent and economically relevant.

Fourth, the evidence from Peru suggests that the effects on foreign exchange returns of sterilised, discretionary and unannounced intervention are significant but also transitory. The evidence on the effect of intervention on the volatility of returns is mixed. On the one hand, an analysis of return volatilities indicates that volatility tends to fall after intervention on intervention days (while it rises on non-intervention days). On the other hand, the effects of intervention on volatility are not significant in event study regressions. However, given the much larger size of intervention (relative to market turnover) and lower volatility of returns in Peru, one explanation is that success at stabilising exchange rate volatility (possibly by influencing expectations) masks the relationship between intervention and volatility in a regression.

Fifth, an analysis of Colombian data suggests that intervention appears to increase market turnover before it takes place and on impact but the effect later declines. This could imply more market disagreement about the direction of the exchange rate before intervention, and greater agreement after it.

To conclude, the preceding results suggest that while serving the goals of foreign reserve accumulation or of supplying foreign currency liquidity to the foreign exchange market, non-discretionary (rule-based) foreign exchange market operations in Latin America have had at times significant but limited or transitory effects on the exchange rate, thus posing little risk of distorting pricing in foreign exchange markets. However, these effects may be understated because they do not take into account how announcements of intervention programmes affect the exchange rate; the experience of Chile suggests that these effects may be significant and persistent. In Peru, where intervention was much larger, and intervention was discretionary and not preannounced, the effects of intervention on returns appear to have been significant, although also transitory.

---

45 A structural VAR analysis that distinguishes between central bank purchases and sales of foreign currency also suggests that intervention in Peru is effective. See Lahura and Vega (2013).

</tbody>
</table>

#### Treatment (intervention) sample

- 5 January 2011 to 30 November 2011 and 5 April 2008 to 29 September 2008
- 387 days. Three rounds of intervention from 24 June 2008 to 30 September 2011: (i) 24 June 2008 to 6 October 2008; (ii) 3 March 2010 to 30 June 2010; and (iii) 15 September 2010 to 30 September 2011. In all rounds, the Bank of the Republic bought USD. The sample starts immediately after a period of fully discretionary intervention which ended on 1 May 2007
- 9 October 2008 to April 2010, with a positive allocation of dollars
- 124 intervention days out of 568 days in sample

#### Control (non-intervention) sample

- All the non intervention days in the sample since 2003
- Sample 1: days between April 12, 2010 and November 29, 2011 with no interventions.
- Sample 2: days between October 9, 2008 and April, 2010 where no dollars were allocated during the auctions. Again, this could be because the auction did not take place or it did take place but no dollars were allocated.

---

1. *Next-day* trades are excluded from the dataset because this market is too shallow and represents less than 5% of the Forex market.
### Other considerations

<table>
<thead>
<tr>
<th>Chile</th>
<th>Colombia</th>
<th>Mexico</th>
<th>Peru</th>

</thead>
<tbody>
<tr>
<td>The first intervention programme was supposed to end on 12 December 2008 but it was ended before, on 29 September 2008. The daily amount purchased was the same as announced so this implied that a smaller amount of foreign exchange reserves was accumulated.</td>
<td>Whenever there is a (usually small) residual amount not allotted in the auction, it is carried forward to the next day. Therefore, a slight variation around the USD 20 million target may be observed between the days of an intervention round. An intervention round may be extended or finished any time after a public announcement by the CCB.</td>
<td>In the context of treatment sample and control sample 2, while we have defined these in terms of days, the key unit is the time window surrounding an event. For instance, if at 9:30 hrs. a positive quantity of dollars is allocated and at 11:30 hrs. no dollars are allocated, the former is part of the treatment sample and the latter is part of the control sample 2.</td>
<td></td>
